Abstract:**Background:** Common obstetric emergencies require blood and blood components transfusion. The use of blood and its components has become a lifesaving strategy in management of obstetric hemorrhage. This study was aimed to know what transfusion practices during emergencies in obstetrics cases should be.**Methods:** A review of 1250 patients of obstetric emergencies requiring blood and its component transfusion was done.**Results:** Requirement of blood and blood components transfusion in obstetric emergencies in one-year period was 20.4%. Mostly multiparous women required blood transfusions (58.12%) and belonged to rural areas (69%). Anemia is a risk factor for obstetric emergencies and the mean pre-transfusion hemoglobin \pm SD was 7.54 ± 1.0 (g/dl). Obstetric hemorrhage (59.6%) was the most common indication for transfusion and packed red cells were most commonly (60.07%) transfused. The overall percentage of adverse reactions seen during transfusion was 1.54%.**Conclusions:** The present study reinforces the importance of Proper transfusion practices during obstetrics emergencies. Specific blood component use avoids many of the hazards associated with use of whole blood. All blood components should be made available at peripheral hospitals as most of the patients require specific blood component and they are referred to tertiary care centre in emergencies which can be avoided.**Keywords:** Blood Component Transfusion, Blood Transfusion, Obstetric Emergencies, Transfusion Adverse Reactions.This is an Open Access article that uses a funding model which does not charge readers or their institutions for access and distributed under the terms of the Creative Commons Attribution License (<http://creativecommons.org/licenses/by/4.0>) and the Budapest Open Access Initiative (<http://www.budapestopenaccessinitiative.org/read>), which permit unrestricted use, distribution, and reproduction in any medium, provided original work is properly credited.**Introduction**

Major obstetric hemorrhage remains the leading cause of maternal morbidity and mortality worldwide. Even though blood transfusion may be a life-saving procedure, an inappropriate usage of blood products in obstetric emergencies especially in cases of massive bleeding is associated with increased morbidity and risk of death.

Blood transfusion services are vital to maternal health because obstetric hemorrhage has been the foremost cause of maternal mortality in India. Pregnancy although a physiological state, can turn pathological suddenly and unexpectedly if not cared for.

Common obstetric emergencies which require blood and blood components transfusion are acute blood loss in first half of pregnancy due to

conditions like complications of abortions, ectopic pregnancy rupture and vesicular mole.

In later half of pregnancy, there can be hemorrhage due to placenta previa or accidental hemorrhage. During labour, women may present with severe anemia and may develop third stage hemorrhage or other complications resulting in severe blood loss and sudden deterioration in general condition can occur.

The appropriate use of blood implies that the transfusion has become inevitable to prevent significant morbidity or mortality.[5] Recently, there has been a tendency to decrease the use of blood transfusion in obstetric practice, the reason for this being risk of transfusion of blood-borne diseases, as well as better pharmacological,

surgical, and mechanical innovations.

The use of blood and its components has become a lifesaving strategy in management of obstetric hemorrhage in general and PPH in particular.

Although the blood transfusion rate in some studies has been quoted as between 0.16% and 6% in obstetrics, transfusion rates vary among countries, hospitals, and doctors due to different practices. In high resource countries the frequency of blood transfusion in obstetrics is reported to be 0.2%–3.2%,[8] while a rate of 2.2% has been reported by a study in a resource-poor country like Nigeria.[9] The rates of blood transfusion vary among different clinicians, with junior doctors and surgical specialists more likely to transfuse patients than physicians and anesthesiologists.[10]

Anemia of pregnancy is defined as hemoglobin concentration <11g/dl in 1st and 3rd trimester and below 10.5 g/dl in 2nd trimester. Early correction of anemia avoids the need for transfusion and reduces maternal mortality. The decision of transfusion should be made on both clinical and hematological grounds.[1]

WHO classification of anemia

- Mild: 10-10.9 g/dl
- Moderate: 7-9.9 g/dl
- Severe: 4-6.9 g/dl
- Very severe: < 4 g/dl.

Transfusion is almost always indicated when Hb is less than 7 g/dl to reduce the rate of maternal morbidity and mortality.[2] In India the prevalence of anemia is around 65-75%.[3]

Obstetric hemorrhage is defined as any blood loss associated with pregnancy or parturition which may be revealed or concealed and is likely to endanger life. Patients usually present with shock which requires urgent blood and its components transfusion. According to sample registration survey (1997- 2003), postpartum hemorrhage accounts for nearly 38% of all maternal deaths.[4]

The management of obstetric hemorrhage is more challenging than hemorrhage in non-pregnant patients because of hypervolemia of pregnancy by approximately 50%. Signs of hypovolemia occur relatively late because of physiological changes in pregnancy. The extent of intravascular volume deficit is not reflected by visual estimates of vaginal bleeding.[5] Role of blood transfusion in acute hemorrhage is to maintain tissue oxygenation and reversal or prevention of coagulopathy using appropriate blood component.

Blood and blood components that can be used:

- RBC'S can be transfused either as whole blood or as packed red cells. Packed red cells are the one and only blood product that provides

oxygen carrying capacity and are one of the most appropriate therapies for patients who require red blood cells due to haemorrhage.

- Fresh frozen plasma: FFP's should be given for coagulation abnormalities, micro-vascular bleeding when PT and PTI are > 1.5 times the mid-rangenormal reference values.
- Platelets: Obstetrical patients with micro-vascular bleeding often require platelet transfusions when platelet count < 50,000/mm [3]
- Cryoprecipitate: Cryoprecipitate is extracted from thawing FFP's slowly and is rich in fibrinogen, fibronectin, factor 13, factor 8 and Von Willebrand's factor. These precipitates can be transfused immediately within 6 hours after thawing.
- Leucocyte depleted blood: Leuko reduction is the removal of white blood cells from the blood or blood components supplied for blood transfusion. Leucocyte removal from blood components is known to prevent or at least delay leucocyte mediated adverse reactions.

Worldwide more than half a million women die each year during childbirth or in postpartum period. Because of unpredictable nature of postpartum bleeding, blood transfusion is recognized as one of the eighth essential components of comprehensive emergency obstetric care, which has been shown to reduce rates of maternal mortality.[6]

The appropriate and rational use of blood and its components is essential for ensuring availability for the needy as well as preventing risk of transfusion-transmitted diseases and transfusion reactions like allergic reactions, acute immune hemolytic reaction, delayed hemolytic reactions etc.

Rational use means providing the right blood or its components in the right quantity, to the right person and at the right time bridging demand and supply gap. Every year, millions of people are exposed to avoidable, life-threatening risks through the transfusion of unsafe blood.

In developing countries like India efforts should be done to make blood transfusion services well maintained and quickly available to reduce maternal morbidity from hemorrhage and thus decrease the incidence of maternal mortality. Because of increasing number of patients requiring blood transfusions due to obstetric emergencies and at the same time adverse reactions encountered, this study is aimed to know the prevalence, indications and adverse reactions of blood and its components transfusion in our set up at MY hospital model blood centre MGM medical college Indore, Madhya Pradesh.

Methods

All patients requiring blood transfusions due to

obstetric emergencies at MGM medical college and associated hospital came to department of obstetrics and gynecology, Indore were included in the study over a period of one year from June 2022 to June 2023.

Inclusion Criteria

All patients requiring blood and its components transfusion in the antepartum, intrapartum and postpartum period due to any obstetric emergency like ectopic pregnancy, abortions, antepartum hemorrhage, postpartum hemorrhage, severe anemia with features of cardiac failure, or any other obstetric emergency requiring blood and its components transfusion were included in the study.

Exclusion Criteria

All obstetric patients requiring planned blood and blood components transfusions.

Study made a record of number of transfusions, type of transfusion, indication of transfusion, any adverse reaction due to transfusion and post

transfusion hemoglobin.

Statistical Analysis

At the end of the study, statistical calculations were performed using the SPSS 16.0 software. Student's t-test was used for comparison of mean values and p value <0.05 was considered as statistically significant. The present study has been carried out with the objective of assessing the prevalence of blood and blood components transfusion among antenatal and postnatal patients with obstetric emergencies, to study the indications of transfusion among these patients and to study the adverse effects of blood and blood components transfusion in these patients. A total number of 405 patients were included in the study.

Results

A total number of 1250 patients were enrolled in the study with a mean age of 24 ± 3.68 years and with majority of them belonging to rural areas (69%).

Table 1: Parity status

Parity	No. of patients	Percentage
P0	149	11.92%
P1	375	30%
$\geq P2$	726	58.02%

Details on Parity status and pre-transfusion hemoglobin levels are in Table 1 and Table 2. Majority of the patients (58.02%) were multiparous ($\geq P2$) and had pre-transfusion mean hemoglobin of 7.04 ± 1 g/dl. Mean post-transfusion hemoglobin was 9.01 ± 0.51 g/dl.

Table 2: Pre-transfusion hemoglobin

Hemoglobin (g/dl)	No. of patients	Percentage
<7.0	376	30.08%
7.0-9.9	701	56.08%
≥ 10.0	173	13.84%
Mean haemoglobin \pm SD	7.04 ± 1	

Most common indication of blood transfusion was early trimester haemorrhage with ruptured ectopic being the most common etiology (Figure 1).

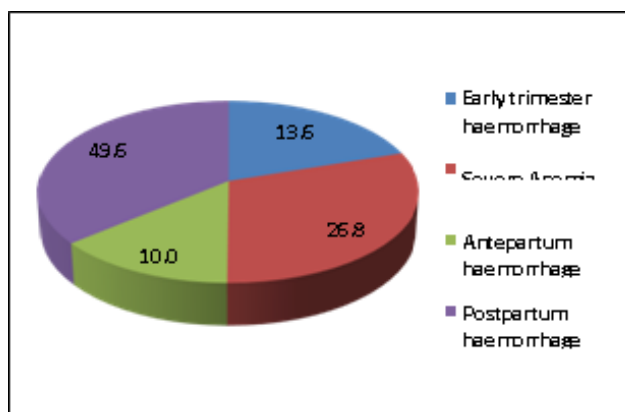

Figure 1: Indications of blood transfusion

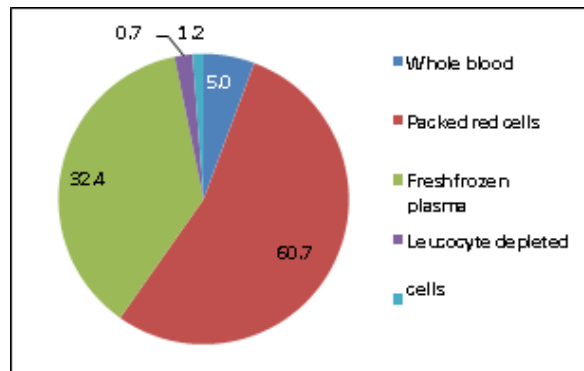

Figure 2: Type of blood and blood components transfusion

Packed red cells were the most common type (60.7%) of blood product used for transfusion (Figure 2).

The adverse reactions of blood transfusions were seen in 1.54% of total patients.

Discussion

Obstetric emergencies can occur suddenly and unexpectedly. These can be life threatening to mother, fetus or both, bleeding can be catastrophic and timely.

intervention is important. The World Health Organization estimates that at least 88-98% of maternal deaths can be averted with timely access to existing emergency obstetric care using effective and efficient referral system. Blood transfusion remains a life-saving practice to millions of women annually; it is an adjunct to good obstetric care with obstetric hemorrhage and severe anemia being some of the most common indications. Obstetric emergencies associated with urgent need for blood may grow direr if not managed effectively.

This study was conducted keeping in view the requirement of blood and blood components transfusion in obstetric emergencies. All patients requiring blood and its components transfusion in obstetric emergencies were included in the study.

The prevalence of blood and blood components transfusion in obstetric emergencies was 20.4% in this study. In another study, incidence of blood and its components transfusion was found to be 14.4%. [7]

The maximum number of patients 534 (42.7%) were in the age group of 22-28 years in this study, which was comparable to the results found in a study by Chawla S et al, in India where majority of patients receiving blood transfusion were in the age group of 21-30 years and in the study conducted by Fazal S et al, in Kerala where maximum number of patients were in the age group of 20-29 years. [8,9] Also in another study, it was reported that the risk of blood transfusion was more in extremes of age. [10] While observing the parity status we found that 58.02% of women who received blood transfusions were multiparous with at least 2 previous viable births. In a study by parul vaid et al

al, 50.2% of women were multiparous and had at least 2 previous viable births. [7] Bindal J et al, also found that maximum number of patients (50%) in the study were multigravida. 11 Also in a study by Chowdhury F et al, done in Bangladesh, 68.3% of women were multiparous. [12] So, multiparity as such is a risk factor and these patients require utmost care in their management.

In this study the majority of patients (69%) were resident of rural areas while 31% patients were resident of urban areas. In another study, it was found that 57% of patients were resident of rural areas and 43% of patients were resident of urban areas. [13] This indicates that urbanization and availability of proper services and education can reduce the requirement of blood transfusion in obstetric emergencies as patients can access medical care early.

Mean pre transfusion hemoglobin \pm SD in this study was 7.04 ± 1 . (g/dl). So, anemia as such is a risk factor for obstetric emergencies and patients should be screened for anemia during antenatal check-ups. This was similar to study by Singh RK et al, where mean pre- transfusion Hb was 7.84 g/dl. [14] Also in another study it was seen that majority of patients 46.83% were recorded in hemoglobin range of 7-9 (g/dl). [12]

Most of the patients (59.6%) in this study required blood and blood component transfusion because of obstetric hemorrhage where PPH (49.6%) was the most common indication. This was also seen in another study, where 70% patients admitted as obstetrical emergencies, required blood and its components transfusion due to obstetric hemorrhage and 30% required blood and its components transfusion due to severe anaemia. [15] In another study done, 81% of blood transfusions were associated with obstetric haemorrhage. [16] The findings in this study are also in accordance with those reported by Chhabra et al, where obstetric hemorrhage and severe anemia were the major indications of blood and its components transfusion in obstetric emergency cases. [17]

The various causes of obstetric hemorrhage were divided into early trimester hemorrhage, antepartum hemorrhage (APH) and postpartum hemorrhage (PPH) for the purpose of the study. Overall PPH (49.6%) was the most common indication of blood and blood components transfusion in this study. Next common cause was severe anemia (26.8%) in antepartum and postpartum patients. These findings were also seen in study by Patel VP et al, where PPH accounted for 36% of the cases and severe anemia accounted for 34% of the cases.[15] This can be attributed to the fact that the hospital is a tertiary care centre where patients with obstetric emergencies are mostly referred from peripheral hospitals. Anemia can be managed at peripheral hospitals but all cases of PPH with shock are mostly referred to this centre for further management because of unavailability of blood components at peripheral hospitals. Therefore, in this study PPH has surpassed anemia as most common cause of blood and its components transfusion in obstetric emergencies.

The overall percentage of adverse reactions seen during transfusion in this study was 1.54% with shivering and fever being the most common. In a review article on rational use of blood and its components in obstetrics-gynecological practice it was given that 1% of all the transfusions lead to some adverse reaction.[17]

Conclusion

This study showed that severe obstetric hemorrhage is a relatively frequent complication. The present study reinforces the importance of appropriate use of blood and its components in obstetric emergencies. Blood transfusion is need of the hour in acute blood loss as this not only prevents mortalities but also decrease morbidities associated with it. It is indispensable for saving lives of mothers who need comprehensive emergency obstetric care services because of pregnancy related hemorrhage, severe anemia or abortions.

As it is rightly said that prevention is better than cure, thus during nine months period, obstetrician must encourage pregnant women to maintain their hemoglobin level in normal range.

Moderate anemia may be treated with intravenous iron therapy in third trimester, so that hemoglobin rise takes place over few weeks' time. Appropriate use of blood components avoids many of the hazards associated with use of whole blood. Particular emphasis should be placed on active management of third stage of labour to prevent avoidable morbidities such as PPH, retained products of conception, vaginal lacerations etc. which require blood and its components transfusions. All blood components should be made available at peripheral hospitals as most

of the patients require specific blood component and they are referred to tertiary care centre in emergencies which can be avoided.
